(Received 2019/8/31)

In the scattering experiments with the MAIKo TPC, we can project tracks of charged particles onto two planes perpendicular and parallel to the beam axis and acquire these projections as two images. It is, therefore, necessary to analyze these two-dimensional images to reconstruct the original three-dimensional tracks. Conventionally, we analyze them with the Hough transformation which is a method to find lines in images. This conventional analysis method requires complex algorithms and large computing power. Recently neural networks have been widely employed for the image recognition. In the present work, we developed a new analysis method for the MAIKo TPC using neural networks. This new method successfully makes the analysis faster and more accurate than the conventional method.

**KEYWORDS:** neural networks, time projection chamber (TPC), active target, MAIKo TPC

## 1. Introduction

Time projection chambers (TPCs) are widely used to detect tracks of charged particles. We developed a TPC using a micro pixel chamber ( $\mu$ -PIC) [1] named MAIKo ( $\mu$ -PIC based active target for inverse kinematics.) [2] for unstable nuclei experiments. Figure 1 shows the schematic view of the MAIKo TPC. When charged particles pass through the detection gas filled in the MAIKo TPC, electrons are emitted along the particle tracks. These electrons are drifted downward by an electric field and gas-amplified on the surface on the  $\mu$ -PIC. The anode and cathode electrodes of the  $\mu$ -PIC are segmented into 256 strips which are arranged orthogonally. These strips are aligned at 400- $\mu$ m intervals. Anode strips are parallel to  $x$ -axis and cathode strips are parallel to  $z$ -axis as shown in Fig. 1. Electrical signals induced by the amplified electrons are read out through the anode and cathode strips to determine the  $x$  and  $z$  position of the particle tracks. The vertical position of the tracks along the  $y$ -axis is determined from the drift time of the electrons. The three-dimensional tracks are reconstructed from  $x$ -,  $y$ -, and  $z$ -coordinates.

Incident particles are scattered by target particles in the sensitive volume of the TPC as shown in Fig. 1. Scattered particles escape from the sensitive volume of the TPC and low-energy recoil particles stop inside. Since reaction points are inside the sensitive volume of the TPC, it is possible

**Fig. 1.** Schematic view of the MAIKo TPC.

to detect low-energy particles over a large solid angle.  $H_2$  or He gas is widely used for a target gas but operation of TPC with pure  $H_2$  or He gas is unstable and prone to discharge. Usually, quenching gas with a high tolerance for electric discharges like  $CO_2$  or iso-butane is mixed with a target gas for stable operation of the TPC although the quenching gas causes background events. Recently, the elastic and inelastic alpha scattering on  $^{10}C$  were measured with the MAIKo TPC at Research Center for Nuclear Physics, Osaka University. In this experiment, He (96%) was used as the target gas and  $CO_2$  (4%) was used as the quencher gas.

The tracks of charged particles in each event were projected onto the plane that is perpendicular to the anode strips and the plane that is perpendicular to the cathode strips, and were recorded as the anode and cathode images. The MAIKo TPC outputs two images in each event. Figures 2 and 3 are examples of the acquired images. These black-and-white images with  $1024 \times 256$  pixels present drift times on the 256 strips of the anode and cathode recorded at every 10 ns for the duration of  $10 \text{ ns} \times 1024 = 10.24 \mu\text{s}$ . Figure 2 shows the anode and cathode images from a  $^{10}C + \alpha$  event in which the incident  $^{10}C$  beam was scattered at the small angle from the beam axis and the  $\alpha$  particle was recoiled at the large angle. On the other hand, Fig. 3 is from a background event due to the quenching gas because the incident  $^{10}C$  beam was scattered at the large angle off a heavy nucleus. For the  $^{10}C + \alpha$  events, the energy and emission angle of the recoil  $\alpha$  particle must be determined to obtain the spectroscopic information such as the excitation energy of  $^{10}C$  and the scattering angle in the center-of-mass system. The energy of the recoil  $\alpha$  particle is determined from the length of the track in the detection gas and the emission angle is determined from the opening angle between the incident particle and the recoil  $\alpha$  particle. To analyze the anode and cathode images, there are two steps.

- Select  $^{10}C + \alpha$  events from background events.
- Determine the length and the emission angle of the recoil  $\alpha$  particle from anode and cathode images.

However, the conventional analysis method requires a lot of efforts to select events and determine tracks from the anode and cathode images. Therefore, we needed to develop a new analysis method using neural networks which are widely employed for the image recognition in recent years.

**Fig. 2.** Typical examples of the anode and cathode images recorded in a  $^{10}C + \alpha$  event

**Fig. 3.** Same with Fig. 2 but recorded in a background event.

## 2. Conventional analysis method

Conventionally, the Hough transformation was used in order to select the  $^{10}C + \alpha$  events and to determine tracks. The Hough transformation is one of methods to find lines from an image. In the

Hough transformation, a hit pixel in the image at  $(x_i, y_i)$  is transformed into a curved line in the  $(\theta, r)$  parameter space (Hough space) according to Eq. (1).

$$r = x_i \cos \theta + y_i \sin \theta. \quad (1)$$

A point at  $(\theta_j, r_j)$  in the Hough space corresponds to a straight line in the original image as given by Eq. (2).

$$y = -\frac{x}{\tan \theta_j} + \frac{r_j}{\sin \theta_j}. \quad (2)$$

When the pixels in the anode or cathode image lie on a straight line, their transformed curves intersect at one point at  $(\theta_j, r_j)$  in the Hough space. Thus, the intersection point in the Hough space gives the particle track according to Eq. (2).

It is possible to select the  $^{10}\text{C} + \alpha$  events by utilizing information about the straight lines extracted from the anode and cathode images such as number, position, angle and length. Once the  $^{10}\text{C} + \alpha$  events are selected, the energy and angle of the recoil  $\alpha$  particle are determined from the images to calculate the excitation energy and the scattering angle in the center-of-mass system. However, the conventional method with the Hough transformation requires a complicated algorithm with many adjustable parameters, and the optimization of these parameters needs large computing power. It takes about 24 hours to optimize the parameters using 100 CPUs, and about one second to process the anode and cathode images from one event using one CPU after the parameter optimization. The accuracy of the event selection was rated 89% using 3,000 events, which were tagged with human eyes.

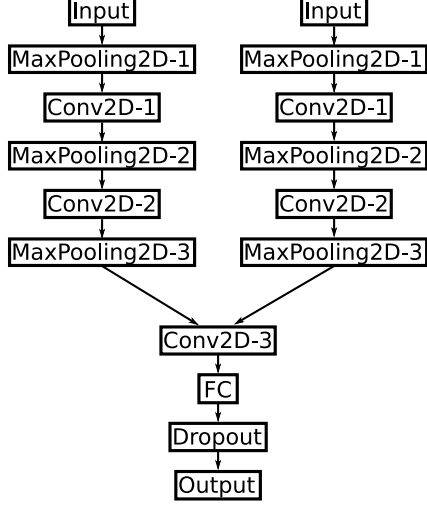

### 3. New analysis method

The conventional method has problems of requiring complex algorithms and large computing power. We developed a new method using neural networks that have been employed for the image recognition recently. Using neural networks, it might be possible to recognize images considering many features of tracks at the same time without any complicated algorithms. Once a neural network trained, the neural network is able to recognize images faster and more accurate than the conventional method.

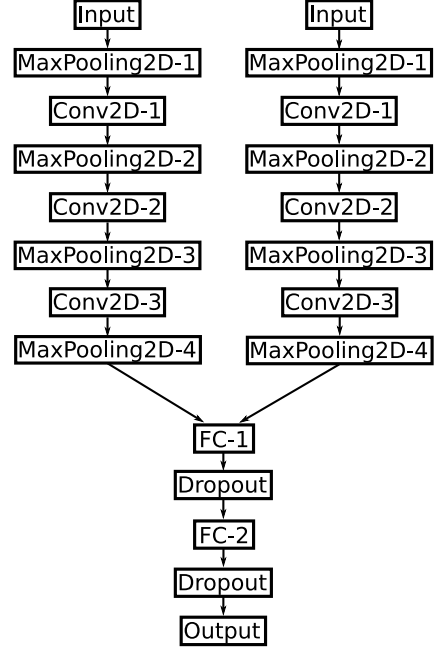

We used a convolutional neural network (CNN) that is useful for image recognition, because the data from the MAIKo TPC are images. Since the analysis consists of the event selection and the track determination, we used two networks to analyze. Figures 4 and 5 show the networks for the event selection and the track determination, respectively. Because the anode and cathode images have different features, the network has two branches. We inputted pair of images from the MAIKo TPC to the neural network. The network for the event selection has 16 layers and the network for the track determination has 21 layers. “Input”, “MaxPooling2D”, “Conv2D”, “FC”, and “Output” in Figs. 4 and 5 shows the input layer, maxpooling layer, convolutional layer, full connection layer, and output layer respectively.

In the event selection, we obtain a probability that the pair of images were taken in the  $^{10}\text{C} + \alpha$  event from output layer. If the probability was larger than 50%, the event was regarded as the  $^{10}\text{C} + \alpha$  scattering. This network was trained and evaluated with the images tagged by eye scan. 2,700 events were used for the training, and other 300 events were for the evaluation. In the track determination, the network outputted the coordinates of two endpoints of a track of a recoil  $\alpha$  particle in a  $^{10}\text{C} + \alpha$  event in which the recoil  $\alpha$  particle stopped in the sensitive volume of the MAIKo TPC. This network was trained and evaluated with the images processed by the conventional method. 3,012 events were used for the training, and other 1,554 events were for the evaluation.

We used Intel Core i7, Nvidia GeForce GTX 1080Ti, Ubuntu 18.04 LTS, and TensorFlow [3] + Keras [4] in the present analysis.

**Fig. 4.** Schematic structure of the neural network for the event selection.

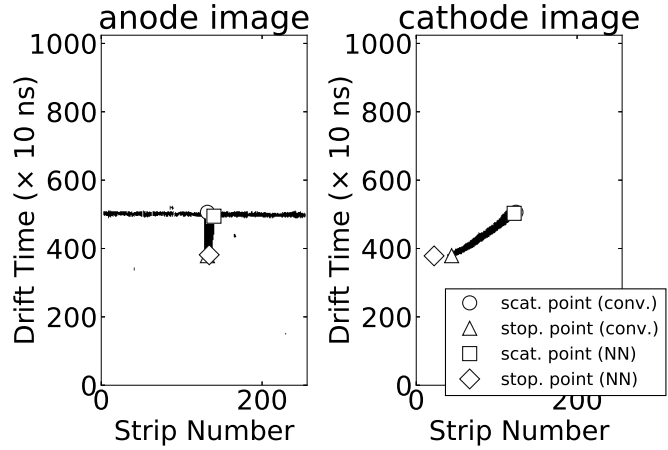

**Fig. 5.** Schematic structure of the neural network for the track determination.

#### 4. Result

The neural network for the event selection was trained 200 times for 2,700 events. It took about 26 minutes for the training and about one second to process for 300 events. The accuracy of the event selection by the neural network was 96%, while the accuracy by the conventional method was 89%. The neural network is able to select events faster and more accurate than the conventional method.

The neural network for the track determination was trained 500 times for 3,012 events. It took about 270 minutes for the training and about two seconds to process 1,554 events. The track endpoints determined by the neural network are compared with those by the conventional method in Fig. 6 in a typical event. The circles and triangles show the scattering and the stopping points determined by the conventional method, while the squares and rhombuses show those determined by the neural network. The differences in the coordinates of the track endpoints determined by the conventional method and the neural network are about four mm in the standard deviation for the 1,554 events. The processing time for the neural network to find the track endpoints became much shorter than the conventional method.

**Fig. 6.** Comparison of the track endpoints determined by the conventional method and the neural network.

## 5. Conclusion

We developed a new method with neural networks to analyze the track images acquired by the MAIKo TPC. It was found that this new method made the event selection and the track determination faster and more accurate than the conventional method with the Hough transformation.
